Models

Angela's paper (Toepp et al., 2019, https://doi.org/10.1371/journal.pntd.0007058) uses logistic regression, with age, sex, and variables that have to do with diagnostic tests as explanatory variables. They are something like this:

Model A 1: $logit(\pi_k) = \beta_0 + \beta_1 A g e_k + \beta_2 S e x_k + \beta_3 Y_k$, where Y_k is diagnostically positive (as defined in Model 1 below), but for the mom and π_k is the probability of disease for individual k

Model A 2: $logit(\pi_k) = \beta_0 + \beta_1 A g e_k + \beta_2 S e x_k + \beta_3 T_{1k} + \beta_4 T_{2k}$, where T_{jk} is the result for Test j (as defined in Model 1 below), but for the mom and π_k is the probability of disease for individual k

Note, these models were fit with a log link function, presumably so that relative risks could be recovered?

We plan to evaluate similar models for our data and to then incorporate sensitivity and specificity of the tests into these models. Then we will compare the model performance to that of other methods. Hopefully we will see an improvement/some details that we miss when we do not include the sensitivity and specificity for the tests.

In all these models, we will assume that the observations are independent.

Model 1:

Data Model

where
$$\pi_{1k} = P(T_{1k} = 1 | D_k) = D_k \times \underbrace{P(T_{1k} = 1 | D_k = 1)}_{sensitivity} + (1 - D_k) \times \underbrace{(1 - P(T_{1k} = 0 | D_k = 0))}_{1-specificity}$$
.

where $\pi_{2k} = P(T_{2k} = 1 | D_k) = D_k \times \underbrace{P(T_{2k} = 1 | D_k = 1)}_{sensitivity} + (1 - D_k) \times \underbrace{(1 - P(T_{2k} = 0 | D_k = 0))}_{1-specificity}$.

Process Model

$$D_k \sim Bernoulli(\delta_k)$$

where
$$\delta_k = logit^{-1}(logit(\rho) + \mathbf{x}_k^T \boldsymbol{\beta}).$$

Prior Model

Prevalence

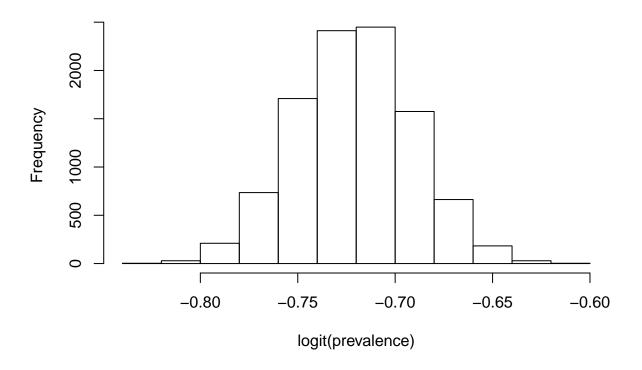

$$logit(\rho) \sim Normal(\mu_{\rho}, \tau^2)$$

where $\mu_{\rho} = logit^{-1}(\rho^*)$ and $\tau^2 = \dots$

We have a range for the prevalence of (0.05, 0.10). This corresponds to a range of (-0.7497, -0.6972) on the logit scale.

```
hist(rnorm(10000, mean = log(0.075)/(1-log(0.075)), sd = 0.03),
    main="Logit prevalence prior distribution histogram",
    xlab="logit(prevalence)")
```

Logit prevalence prior distribution histogram

Note, the prevalence in this population may be higher - these are exposed dogs in the United States in our hunting hound population. We may want to change this, but we also want to generalize this to the larger canine population - to Brazil, if possible.

Linear predictors

The regression parameters are $\beta = (\beta_{age}, \beta_{sex}, \beta_{age*sex})^T$;

$$\boldsymbol{\beta} \sim Normal(\boldsymbol{\mu}_{\beta}, \boldsymbol{\Sigma}_{\beta})$$

where $\mu_{\beta} = 0$ and $\Sigma_{\beta} = I$ in our code.

Model 2:

The data outcome we are using is "diagnostically positive", meaning that an individual tests positive on at least one diagnostic test. This is what we have used in our other papers and seems to be popular in the literature (add some references to this). In this model, we assume that the two diagnostic tests are independent, and that there is some imprecision in the test results, so we include sensitivity and specificity for each test in the model.

Data Model

$$Y_k|T_{1k},T_{2k},D_k \sim Bernoulli\left(\pi_k^{DP}\right)$$

We are assuming that the test outcomes are independent. The probability of a diagnostically positive test for individual k, π_k^{DP} , is

$$\pi_k^{DP} = P(Y_k = 1 | D_k)$$

= $D_k \times P(Y_k = 1 | D_k = 1) + (1 - D_k) \times (1 - P(Y_k = 0 | D_k = 0)),$

where $P(Y_k = 1 | D_k = 1) = P(T_{1k} = 1 | D_k = 1) + P(T_{2k} = 1 | D_k = 1) - P(T_{1k} = 1 | D_k = 1) \times P(T_{2k} = 1 | D_k = 1)$ and $P(Y_k = 0 | D_k = 0) = P(T_{1k} = 0 | D_k = 0) \times P(T_{2k} = 0 | D_k = 0)$.

Process Model

$$D_k \sim Bernoulli(\delta_k)$$

where $\delta_k = logit^{-1}(logit(\rho) + \mathbf{x}_k^T \boldsymbol{\beta}).$

Prior Model

Prevalence

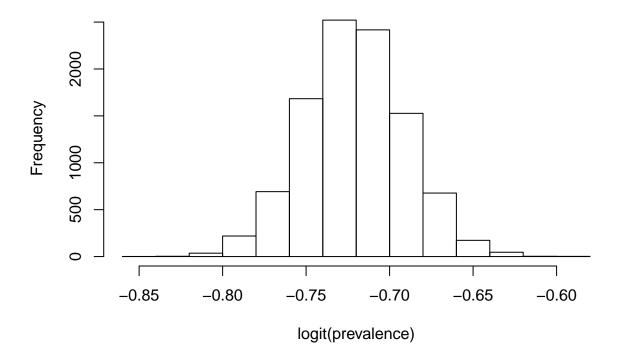

$$logit(\rho) \sim Normal(\mu_{\rho}, \tau^2)$$

where $\mu_{\rho} = logit^{-1}(\rho^*)$ and $\tau^2 = \dots$

We have a range for the prevalence of (0.05, 0.10). This corresponds to a range of (-0.7497, -0.6972) on the logit scale.

```
hist(rnorm(10000, mean = log(0.075)/(1-log(0.075)), sd = 0.03),
    main="Logit prevalence prior distribution histogram",
    xlab="logit(prevalence)")
```

Logit prevalence prior distribution histogram

Note, the prevalence in this population may be higher - these are exposed dogs in the United States in our hunting hound population. We may want to change this, but we also want to generalize this to the larger canine population - to Brazil, if possible.

Linear predictors

The regression parameters are $\beta = (\beta_{age}, \beta_{sex}, \beta_{age*sex})^T$;

$$\boldsymbol{\beta} \sim Normal(\boldsymbol{\mu}_{\beta}, \boldsymbol{\Sigma}_{\beta})$$

where $\mu_{\beta} = 0$ and $\Sigma_{\beta} = I$ in our code.

Prior Model

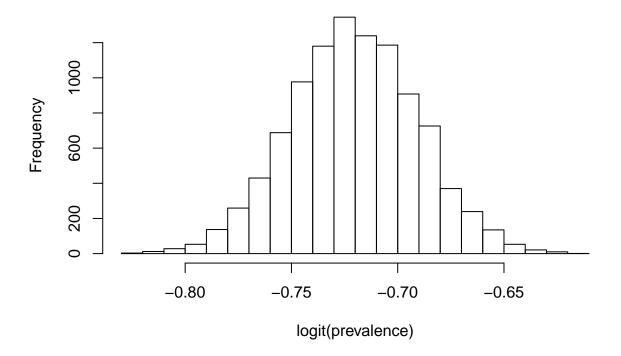

Prevalence:

$$logit(\pi) \sim Normal(\mu_{\pi}, \sigma_{\pi}^2)$$

We have a range for the prevalence of (0.05, 0.10). This corresponds to a range of (-0.7497, -0.6972) on the logit scale.

```
hist(rnorm(10000, mean = log(0.075)/(1-log(0.075)), sd = 0.03),
    main="Logit prevalence prior distribution histogram",
    xlab="logit(prevalence)")
```

Logit prevalence prior distribution histogram

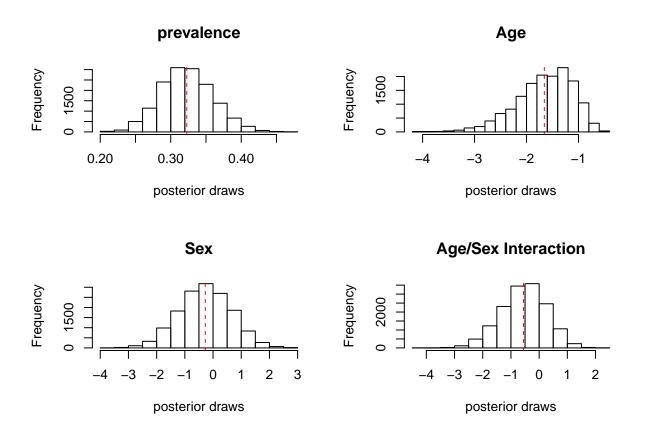

Other parameters:

$$\boldsymbol{\beta} \sim Normal(\boldsymbol{\mu}_{\beta}, \boldsymbol{\Sigma}_{\beta})$$

We will assume that the regression coefficients are independent, so Σ_{β} is a diagonal matrix.

OpenBUGS Model 2 Implementation

```
par(mfrow=c(2,2))
## Graphial summaries of posterior distribtuions
hist(exp(model2_df$lpi)/(1+exp(model2_df$lpi)), main="prevalence", xlab="posterior draws")
